# **Mitochondrial Transplantation: Adaptive Bio-enhancement**

#### **Abstract**

Mitochondria, known as the powerhouse of the cell, are essential for cellular energy production. Dysfunction in mitochondrial function can significantly affect various organs. Transplanting healthy mitochondria can enhance the bioenergetics of diseased cells and treat various conditions, yet the limits of mitochondrial transplantation are still unknown. Our study reveals that the source of transplanted mitochondria is not restricted by species, and recipient cells show no significant immune response to mitochondria from different lineages. We also found that metabolic compatibility between the recipient and exogenous mitochondria is crucial, and transplanting mitochondria from different species can endow recipient cells with distinct characteristics to combat diseases. Furthermore, our data indicate that there is competition among mitochondria with varying functions, with more powerful mitochondria yielding better therapeutic effects. Notably, we have not yet found an upper limit for the bio-enhancement provided by exogenous mitochondria. Our research proposes a feasible path for human bio-enhancement through mitochondrial transplantation-adaptive bio-enhancement.

# **Introduction**

Mitochondrial transplantation involves isolating mitochondria from normal cells or tissues and transferring them to diseased areas either directly or indirectly to improve the function of damaged cells, thereby aiding in treatment. Compared to organ, tissue, or cell transplantation, mitochondrial transplantation is a novel and milder alternative therapy. In 2009, Boston Children 's Hospital first reported mitochondrial transplantation, injecting mitochondria into ischemic regions of the rabbit heart and observing significant therapeutic effects [1]. To date, mitochondrial transplantation has shown promising therapeutic outcomes in various organ and tissue injuries, including the heart, brain, spinal cord, lungs, kidneys, liver, skeletal muscle, and skin, as well as in conditions such as sepsis and cancer [2-12].

Despite the proven safety and therapeutic efficacy of mitochondrial transplantation in numerous diseases, its full potential remains unclear [13]. Transplanting functionally normal mitochondria to restore the function of dysfunctional mitochondria in diseased

cells involves differences in mitochondrial function, which enhances the function of diseased cells. Preemptively providing normal cells with exogenous mitochondria can grant them a higher damage threshold, thereby bioenergetically enhancing normal cells [3,14]. The question arises: can we select mitochondria with different characteristics for different disease populations or use mitochondria with functions superior to normal mitochondria as a purely adaptive bioenhancement strategy? This is a topic worth exploring.

In this study, we expanded the sources of mitochondria for transplantation and demonstrated the universality of mitochondrial transplantation. We further utilized the lineagespecific characteristics of mitochondria to treat cells under different disease conditions, highlighting the importance of metabolic matching. Additionally, we obtained hybrid mitochondria with enhanced therapeutic suitability by inducing cell fusion to combine multiple lineage characteristics. Building Xiaomeng Lu\*, Yong Jiang

on this, we discovered that mitochondria with greater functional potency exhibited an overwhelmingly superior therapeutic effect compared to their lineagespecific counterparts, even enhancing the function of normal cells to some extent. Similar results were observed in animal experiments, suggesting that mitochondrial transplantation could potentially be used as a means of biological enhancement. This significantly broadens the therapeutic value of mitochondrial transplantation and offers a new research direction for biological augmentation.

# **Universality of mitochondrial transplantation**

Mitochondria, a fundamental and essential organelle present in most eukaryotic cells, have a relatively simple genome structure, typically ranging in size from 15 kb to 60 kb. Their primary function is to supply energy to cells [15,16]. The prevailing theory suggests that mitochondria originated from α-proteobacteria that established a stable endosymbiotic relationship with the host during the process of organelle formation. As the αproteobacteria progressively reduced their protein repertoire and transferred most of their genetic material to the host nucleus, this unique evolutionary process likely explains why mitochondria, even when transplanted between different species or across species, do not elicit significant immune or inflammatory responses [15,17-19]. Current research on mitochondrial transplantation primarily uses mitochondria from three sources: various cell lines, human umbilical cord mesenchymal stem cells, and tissues such as liver, skeletal muscle,, brain, and platelets, with the experimental animals mainly being humans, rabbits, mice, pigs, and rats [1,20-33]. We aimed to expand the species origin of mitochondria used for transplantation to enhance the therapeutic potential of this approach.

Using green fluorescent markers, we labeled mitochondria from 13 different animal species, including African Green Monkey Kidney Cells (Vero), Bovine Kidney Cells (MDCK), MDBK Canine Kidney Cells (MDBK), Feline Kidney Cells (CRFK), Porcine Kidney Cells (PK15), Chicken Hepatocarcinoma Cells (LMH), Spodoptera Frugiperda Cells (SF9), turtle liver tissue, bullfrog liver tissue, quail liver tissue, lizard liver tissue, large yellow croaker liver tissue, and eel liver tissue. Through ATP assays, JC-1 staining, transmission

electron microscopy, and mitochondrial respiratory chain complex activity assays, we confirmed that the isolated mitochondria from these species were biofunctionally intact and structurally well-preserved (Figures 1A-1G) . We then co-cultured Mito-Tracker Green-labeled mitochondria from these species with WGA594 red fluorescently-labeled Human Cardiomyocytes (AC16), Human Hepatocarcinoma Cells (HepG2), and Mouse Skin Fibroblasts (L929), observing efficient internalization and significant co-localization of the various mitochondria within recipient cells (Figure 1H).

To evaluate the safety of these interspecies mitochondrial transplants, we collected the supernatants of the co-cultured cells and assessed immune and inflammatory responses using ELISA. We found no significant changes in the levels of IL-6, IL-10, and TNF-α in the mitochondria-transplanted groups compared to normal cells, indicating a high degree of safety for multi-species mitochondrial transplantation (Figures 1I-1N).

Additionally, we included mitochondria from *Vaucheria litorea,* further pushing the species boundary. After labeling these mitochondria with Mito-Tracker Red and co-culturing them with WGA594-labeled L929 cells, we observed that although most of the plant mitochondria were damaged due to extraction techniques, some intact ones were still internalized by the cells (Figures 1A and 1B). Given the complexity of plant mitochondrial extraction and the significant genetic divergence between plant and animal mitochondria, the safety and efficacy of such transplants would substantially bolster our findings. We conducted *Vaucheria litorea* mitochondrial transplantation every three days for 25 days, initially observing immune responses in the first five transplants. However, starting from the sixth transplant, due to contamination and other factors, IL-6, IL-10, and TNF-α levels surged, leading to cell death (Figures 1C-1F). While the outcome of plant mitochondrial transplantation is largely acceptable, as the extraction of plant mitochondria has a high contamination risk, the initial success of these transplants sufficiently demonstrated the universality and safety of mitochondrial transplantation. The internalization of mitochondria from multiple species reflects the cellular "inclusiveness" to various foreign organelles.

# **Mitochondria with matching metabolic characteristics provide better therapeutic outcomes**

Eukaryotic mitochondria are maternally inherited. Although the gene sequence and composition are relatively conservative, their sequence variation rate is quite fast, which makes the mitochondrial genes differ in different species over a long period of evolution, that is to say, the mitochondria of various species are unique [15,34-40]. Given the universality of mitochondrial transplantation and the ability to transplant mitochondria from various species, we explored whether the species-specific characteristics of mitochondria might lead to different therapeutic outcomes. Additionally, factors such as the physiological state of the donor organism, cell culture conditions, and mitochondrial isolation methods can influence mitochondrial function, raising questions about whether these differences affect therapeutic efficacy.

In organ and stem cell transplantation, metabolic compatibility is crucial for achieving optimal therapeutic outcomes, and mitochondrial transplantation is no exception [34,41,42]. This raises the question: When mitochondrial functions are similar, do metabolically matched mitochondria offer better therapeutic outcomes? I hypothesized that, in the absence of significant functional differences, metabolically matched mitochondria would yield superior therapeutic effects. To minimize variables, we used mitochondria from four different kidney cell species and selected functionally similar mitochondria based on MMP and ATP assessments (Figures 2A, 2B, 2J and 2K). We then co-cultured these mitochondria with cells under different disease model conditions, observing varying therapeutic effects.

In the  $H_2O_2^-$  induced BMDM oxidative stress model, all mitochondrial transplant groups showed significant therapeutic effects, but the MDCK group notably enhanced cell viability compared to the MDBK and Vero groups (Figure 2C) [43]. Immunofluorescence staining revealed a marked reduction in mitochondrial ROS production in all transplant groups, with a significant reduction of mitochondrial ROS in the MDCK group compared to the MDBK group (Figures 2D and 2E). Additionally, lipid peroxidation was significantly decreased, and glutathione levels were notably increased in the MDCK group compared to the Vero group (Figures 2F and 2G). Overall, these results suggest that MDCK mitochondrial transplantation is more effective in treating  $\rm{H}_{2}\rm{O}_{2}$  induced oxidative stress in Bone Marrow-Derived Macrophages (BMDMs). Despite no significant differences in mitochondrial function among the groups based on ATP and MMP analysis, the MDCK group showed a slight advantage (Figures 2A and 2B). To exclude the impact of minor functional differences, we paired MDBK mitochondria with MDCK mitochondria and Vero mitochondria with PK15 mitochondria, labeling them with Mito-Tracker Deep-Red and Mito-Tracker Green, respectively. After co-culturing with  $\rm{H}_{2}\rm{O}_{2}$  treated BMDMs for 24 hours, fluorescent immunostaining showed no significant competition between the different mitochondria, and their internalization levels were comparable (Figures 2H and 2I).

Since there were no significant functional differences among the four types of mitochondria and their internalization levels were similar, the only distinction was their species of origin. Although the primary function of mitochondria is to provide energy, their auxiliary functions, which vary among species, seem to have made the MDCK mitochondria more metabolically compatible with the  $H_2O_2$  treated BMDMs, resulting in better therapeutic outcomes.

ns = no statistical significance,  $* = p<0.05$ ,  $** =$  $p<0.01$ , \*\*\* =  $p<0.001$ , \*\*\*\* =  $p<0.0001$ 

In Carbonyl Cyanide m-chloro Phenylhydrazone (CCCP-treated) AC16 cells, despite similar mitochondrial function based on ATP and MMP assessments, the MDBK group showed no significant advantage (Figures 2J and 2K) [44]. Nevertheless, its therapeutic effect was superior, significantly enhancing cell viability compared to the MDCK and PK15 groups (Figure 2L). The MDBK group also had lower IL-6 levels compared to the Vero group and lower IL-10 levels compared to the MDCK group, although there were no significant differences in TNF-α levels among the groups (Figures 2M-2O). Overall, the MDBK mitochondria exhibited better anti-inflammatory effects in CCCPtreated AC16 cells. Despite the lack of functional advantages, the superior therapeutic outcomes in the MDBK group suggest that its mitochondria were more metabolically compatible with the CCCPtreated AC16 cells. These findings warrant further investigation.

We also extracted mitochondria from the four kidney cell species and co-cultured them with LPStreated HepG2 cells [45]. In this case, despite similar mitochondrial function across groups, the Vero mitochondria exhibited better therapeutic efficacy, significantly enhancing cell viability compared to the MDCK and PK15 groups (Figures 4A-4C). The Vero mitochondria also reduced mitochondrial ROS production compared to the MDCK group and decreased IL-6 levels more effectively than the MDBK group (Figures 4D and 4E). Although IL-10 levels showed no significant differences among the groups, the Vero mitochondria still exhibited a slight advantage (Figure 4F). These results indicate that Vero mitochondria were more effective in treating LPS-induced stress in HepG2 cells, supporting my hypothesis that metabolic compatibility plays a critical role in the therapeutic effects of mitochondrial transplantation. However, the lack of expected results in IL-10 detection and the absence of significant differences in TNF-α levels in CCCPtreated AC16 cells suggest that the compatibility between mitochondrial characteristics and cellular metabolism might have limits. The therapeutic effects of mitochondrial transplantation are primarily reflected in their core functions, and these results may not scale significantly when translated from cell culture to animal models or human treatments. Therefore, further exploration of the

potential to enhance mitochondrial transplantation by integrating the characteristics of multiple mitochondrial species is warranted.

# **Generation of more potent pluripotent hybrid mitochondria through mitochondrial fusion**

Mitochondrial transplantation can endow recipient cells with the characteristics of donor mitochondria. For instance, co-culturing mitochondria from human mammary epithelial cells with breast cancer cells has been shown to inhibit glycolysis, reduce glucose uptake, suppress cancer cell proliferation, and enhance sensitivity to paclitaxel [17]. Similarly, co-culturing mitochondria containing antibiotic resistance genes with antibiotic-sensitive cells can improve resistance to antibiotics [46]. Given that cell fusion can lead to metabolic reprogramming, enabling fused cells to acquire traits from different cell types, a question arises: can mitochondria within fused cells also gain multi-lineage characteristics [47]? Both current studies and my research indicate that mitochondria do not seem to have lineage restrictions, suggesting the potential to create mitochondria with enhanced characteristics through fusion. Could mitochondria with multilineage traits offer superior therapeutic efficacy under equivalent functional conditions?

I conducted a study in which HL-1 and H9C2 cells were fused. The fusion cells were harvested and validated using immunofluorescence and flow cytometry, followed by passaging and subsequent coculture with CCCP-induced mitochondrial damage in AC16 cells (Figure 3A,3B,2C-2F). Mitochondria were extracted from HL1, H9C2, and HL1+H9C2 fused cells and co-cultured with AC16 cells. MMP and ATP assays confirmed that all three groups had well-preserved mitochondrial function with no significant differences (Figures 3C-3D). All groups significantly improved AC16 cell viability, with the HL1+H9C2 group showing the most pronounced effect (Figure 3E). Immunofluorescence analysis revealed that all mitochondrial transplantation groups markedly reduced ROS production in the cells, with quantitative fluorescence data indicating a significant reduction in mitochondrial ROS in the HL1+H9C2 group compared to the H9C2 group (Figures 3F and 3G). Although there was no significant difference in MDA levels among the three groups , the GSH levels were significantly higher in the HL1+H9C2 group compared to the H9C2 group (Figures 3H and 3I). Overall, the HL1+H9C2 group demonstrated superior therapeutic effects on AC16 cells.

Although the therapeutic efficacy of hybrid

mitochondria from fused cells was stronger than that of single-lineage mitochondria, the advantage was not substantial. HL1 and H9C2 cells are phylogenetically close, sharing similar lineage characteristics, which may explain the less pronounced therapeutic effect. Nevertheless, this finding aligns with the conclusion from the second section: mitochondria with better metabolic compatibility exhibit superior therapeutic effects when the mitochondrial biological functions are not much different.

# **Competitive internalization of mitochondria: The fittest functions best**

Natural selection dictates that the fittest survive, a principle that also applies to mitochondrial transplantation [48]. When the bioenergetic function of transplanted mitochondria varies significantly, the more suitable mitochondria may provide better therapeutic outcomes.

Given the variability in bioenergetic function due to differences in the physiological state and rearing environment of animals, I extracted mitochondria from the liver tissues of sparrows, lizards, salmon, and bullfrogs and co-cultured them with CCCPtreated HepG2 cells [49]. ATP and MMP assessments indicated that the mitochondria from bullfrogs exhibited the strongest bioenergetic function among the four groups (Figures 4A and 4B). All four types of mitochondria significantly restored mitochondrial membrane potential, demonstrating their therapeutic potential (Figure 3A). However, the bullfrog mitochondria significantly enhanced HepG2 cell viability compared to the sparrow and lizard mitochondria (Figure 4C). They also markedly reduced mitochondria ROS production compared to the sparrow and salmon groups and better repaired DNA oxidative damage than the other three groups (Figures 4D and 4E). Immunofluorescence further revealed that HepG2 cells internalized a greater quantity of bullfrog mitochondria compared to lizard mitochondria (Figures 4F and 4G). This suggests that while metabolic compatibility is important when bioenergetic function is similar, superior bioenergetic function provides better therapeutic effects when there is a significant difference.

I conducted a similar experiment by extracting

mitochondria from the liver tissues of the four animals and co-culturing them with LPS-treated BMDM cells [50]. ATP and MMP assessments showed that salmon mitochondria exhibited stronger bioenergetic function than the others (Figures 4H and 4I). All four types of mitochondria effectively restored mitochondrial membrane potential in LPStreated BMDM cells (Figure 3B). However, bullfrog mitochondria showed a more significant therapeutic effect by enhancing cell viability and reducing inflammation and DNA oxidative damage compared to the other groups. Bullfrog mitochondria significantly improved cell viability compared to the other three groups, reduced IL-6 levels compared to the salmon and lizard groups, lowered TNF-α levels compared to the other three groups , and decreased IL-10 levels compared to the sparrow and salmon groups. They also reduced 8-OHDG levels more than other three groups (Figures 4J-4N). Immunofluorescence analysis revealed that bullfrog mitochondria were internalized at a much higher rate than lizard and sparrow mitochondria (Figures 4O and 4P). These results indicate that, under equal conditions, cells actively select mitochondria that are more beneficial to them, while mitochondria compete to out-survive each other, demonstrating the classic law of "survival of the fittest.'' Moreover, I cultured P5 generation PK15, P15 generation MDBK, P15 generation MDCK, P15 generation Vero to create mitochondria with varying bioenergetic strengths and co-cultured them with  $H_2O_2^-$  treated HepG2 cells [51]. ATP and MMP assessments revealed that mitochondria from early-passage PK15 cells exhibited stronger bioenergetic function than those from MDBK and Vero cells (Figures 4G and 4H). PK15 mitochondria significantly improved HepG2 cell viability and reduced ROS production compared to MDBK and MDCK cells (Figures 4I and 4J). They also increased GSH levels and decreased MDA production more than MDCK mitochondria, reducing oxidative stress in HepG2 cells, further confirming the therapeutic advantage of mitochondria with stronger bioenergetic function (Figures 4K and 4L).

ns = no statistical significance,  $* = p<0.05$ ,  $** =$  $p<0.01$ , \*\*\* =  $p<0.001$ , \*\*\*\* =  $p<0.0001$ 

The internalization of plant mitochondria also reflects this result. Due to the variability in mitochondrial quality upon extraction, they were categorized into three groups: mostly dead, partially functional, and a small portion that was fully functional. For normal L929 cells, the dead and partially functional mitochondria were excluded, and only the fully functional ones were internalized. However, in L929 cells with mitochondrial and cellular damage, the range of internalization included both partially functional and fully functional mitochondria (Figures 1A-1C). The differential internalization of mitochondria based on cellular and mitochondrial function suggests a form of mutual selection, reflecting the law of "survival of the fittest," where the mitochondria with stronger bioenergetic function are more likely to be internalized and survive.

# **Mitochondrial transplantation enhances physical function and biological potency in mice**

Mitochondrial transplantation temporarily supplements or replaces the mitochondria of recipient cells in the short term. However, the long-term biological outcome involves the bi-fusion and fission of both exogenous and endogenous mitochondria, leading to the formation of new mitochondria. Without continuous supplementation, exogenous mitochondria are eventually assimilated by the recipient cells, causing alterations in the metabolome, proteome, and even genome of the recipient cells [52-54]. However, as the fusion and fission cycles continue, similar to Mendelian inheritance, the influence of the foreign mitochondria diminishes over time, and the benefits they confer gradually fade [55-57]. My in vitro experiments focus on demonstrating the impact of mitochondrial functionality on the efficacy of disease treatment. Only when the potent therapeutic effects of mitochondrial function are established do the germline characteristics and metabolic matching of mitochondria gain significance. Therefore, my in vivo experiments are limited to verifying the short-term therapeutic effects of mitochondrial transplantation on recipient cell function. We need to understand the limits of mitochondrial transplantation to lay the foundation for subsequent germline studies.

Our in vitro experiments indicate that mitochondria with greater functional potency exhibit superior therapeutic effects on diseases compared to mitochondria with normal function. Is this also applicable in vivo? Studies suggest that preemptive administration of normally functioning mitochondria can enhance cellular resistance to stimuli, but does this confer greater benefits to general recipients? Mitochondrial biogenesis, enhanced through training, increases mitochondrial function. Mice with trained mitochondria should, therefore, exhibit better therapeutic outcomes than those with autologous or allogeneic mitochondria with normal function [18,58,59]. The functional enhancement of mitochondria in trained mice is based on their overall physical fitness. Wild-type mice, being more robust with stronger metabolism, are hypothesized to possess even more potent mitochondrial function.

Using a D-gal-induced aging mouse model, we extracted mitochondria from mouse myoblasts (C2C12), young C57B/L 6J (4 months old) gastrocnemius muscle tissue, HIIT- trained C57B/L 6J gastrocnemius muscle, HIIT-trained human gastrocnemius muscle, and wild mouse gastrocnemius muscle for tail vein injection into aged mice, subsequently, mitochondria from the gastrocnemius muscle tissue of HIIT-trained C57B/L6J mice and wild mice were selected for intravenous tail injection into 4-months-old normal C57B/L6J mice [60]. Additionally, we co-cultured mitochondria from each group with normal HepG2 and D-gal-treated HepG2 cells.

ATP and MMP assessments revealed significant differences in mitochondrial function between the Wild Mice group and the C2C12, Young C57, and Trained People groups. There was also a significant difference between the Trained C57 and Young C57 groups, with the Wild Mice group showing a slight advantage over the Trained C57 group, though not statistically significant (Figures 5A and 5B). No immune inflammatory response was observed 24 hours post-surgery (Figure 5A). In the aging model, all groups showed improved exercise performance three days post-transplantation, with the Wild Mice

and Trained C57 groups demonstrating greater endurance (Figure 5C). In the normal model, only the Wild Mice group showed improved endurance. One week post- transplantation, body weight significantly increased in all aging model groups, with the Wild Mice group showing the greatest recovery (Figures 5D-5F and 5I). No significant differences were observed in the normal model groups (Figures 5J and 5K). Although all transplant groups had therapeutic effects, the Wild Mice group more significantly reduced oxidative stress in aged mice, showing lower MDA levels compared to the Young C57 and Trained People groups. NOS levels were lower in the Wild Mice group compared to the C2C12, Young C57, and Trained People groups; although the Trained C57 group also differed significantly from the Young C57 group, it was still inferior to the Wild Mice group (Figure 5G). The Wild Mice group had significantly higher SOD activity compared to the C2C12, Young C57, and Trained C57 groups and also increased SOD activity in normal mice (Figures 5H-5M). Furthermore, mitochondrial transplantation increased the bioenergetic capacity of normal L929 cells, with the Wild Mice and Trained C57 groups showing the greatest enhancement, particularly the Wild Mice group (Figure 5O). All mitochondrial transplant groups partially restored MMP in CCCP-treated L929 cells, significantly reducing ROS production. The Wild Mice and Trained C57 groups had better MMP recovery, more normal mitochondrial morphology, and lower ROS fluorescence intensity (Figures 6A and 6B). Ranking mitochondrial function suggests Wild Mice > Trained C57 > Young C57 ≈ Trained People ≈ C2C12. The observed therapeutic effects support the conclusion that mitochondria with greater functional potency provide better therapeutic outcomes, establishing a positive correlation. Given the robust physical fitness of wild animals, their mitochondria might currently be the most potent. I believe that mitochondrial transplantation has no upper limit but only continues to yield better therapeutic results, which applies to general recipients as well.

ns = no statistical significance,  $* = p<0.05$ ,  $** =$  $p<0.01$ , \*\*\* =  $p<0.001$ , \*\*\*\* =  $p<0.0001$ 

Unfortunately, due to the poor efficacy of D-gal, the two-months treatment failed to adequately reproduce the aging mouse model, resulting in limited experimentation. Consequently, we conducted a second animal experiment, isolating mitochondria from the gastrocnemius muscles of Young C57B/L 6J (4 months old) and Wild Mice for tail vein injection into both acute inflammation mouse model and normal mouse model [61]. We also co-cultured mitochondria from each group with normal and LPS-treated BMDM. ATP and MMP analyses showed that Wild Mice mitochondria had the highest functional potency, with no immune inflammatory response observed after 24 hours (Figures 6C-6D,5B) . Small animal imaging detected the absorption of exogenous mitochondria by severely damaged liver and kidney tissues via the circulatory system (Figure 6E). Three days posttransplantation, grip strength and endurance were significantly restored in all acute inflammation model groups, with the Wild Mice group showing the most notable endurance improvement (Figures 6F-6J). No significant differences in grip strength were observed in the Normal C57 groups, but

the Wild Mice group had significantly improved endurance compared to the Ctrl group (Figures 6F-6K). After one week, body weight had recovered in all acute inflammation model groups, with the Wild Mice group showing a significant increase compared to the LPS group (Figure 6H). No significant differences in body weight were observed in the normal mouse groups (Figure 6I). MRI assessment indicated significant increases in hind limb muscle volume in both the Wild Mice and Young C57 groups in the acute inflammation model, with the Wild Mice group slightly outperforming the Young C57 group (Figures 5D,5E). Muscle tissue damage recovery was also better in the Wild Mice group (Figures 5D,5F). Serum levels of IL- 6, IL-10, and TNF-α were reduced in both the Wild Mice and Young C57 groups after treatment, with the Wild Mice group showing lower levels of IL-10 and TNF-α compared to the Young C57 group, and no significant changes were observed in the normal mouse groups (Figures 7A-7C). Liver and kidney function were significantly improved in the Wild Mice and Young C57 groups, with serum AST levels significantly lower in the Wild Mice group compared to the Young C57 group. No significant differences were observed in the Normal C57 groups (Figures 7D-7F). Both the Wild Mice and Young C57 groups significantly reduced oxidative stress in the acute inflammation model, with lower MDA levels and higher SOD activity in the Wild Mice group compared to the Young C57 group. The Wild Mice group also significantly increased SOD activity in normal mice, although there was no difference in MDA levels among the groups (Figures 7G-7H). Expression of inflammatory proteins in the liver and kidney tissues was reduced in both the Wild Mice and Young C57 groups in the acute inflammation model, with the Wild Mice group showing lower P-JNK protein expression compared to the Young C57 group (Figures 7I-7K). Real-time quantitative PCR showed downregulation of IL-6, IL-8, IL-18, TGF-β, MPO, CXCL1, CXCL2, and HMGB1 and upregulation of IL-13, SOD1, ARG1, and COX1 in the kidneys of the Wild Mice and Young C57 groups compared to the LPS group. In the liver, IL-6, IL-8, IL-18, IL-1β, CXCL2, CCL5, CCL10, and TGF-β were downregulated, while IL-4, IL-13, ARG1, and SOD1 were upregulated , with significant differences between the Wild Mice and Young C57 groups, indicating the superior therapeutic effect of Wild Mice mitochondria(Figures 5G and 5H).

# Mitochondrial Transplantation: Adaptive Bio-enhancement Research

# **Figure 6:** Mitochondrial transplantation enhances physical function.

#### **Outcomes**

- A: Fluorescence imaging of mitochondrial membrane potential in HepG2 cells treated with CCCP 24 hours after transplantation of five different mitochondria, with untreated cells as control. Scale bar: 30 µm.
- B: Fluorescence imaging of Reactive

Oxygen Species (ROS) in HepG2 cells treated with CCCP after transplantation of five different mitochondria, with untreated cells as control. Scale bar: 30 µm.

• C-D: Evaluation of isolated mitochondria functions via ATP production and Mitochondrial Membrane Potential (MMP) assays, with mitochondria subjected to two freeze-thaw cycles at -80°C and 37°C to completely disrupt structure and function as control.

- E: Biodistribution of exogenous mitochondria in mouse liver, kidney, and heart detected by in vivo imaging. 24 hours after intravenous tail vein injection of mitochondria. Blank: untreated LPS model group mice.
- F-H: Body weight changes in acute inflammation model mice and normal mice before and one week after transplantation of two different mitochondria, with untreated groups as control.Grip strength measurement in acute inflammation model mice and normal mice three days after transplantation of two different mitochondria, with untreated groups as control.
- J-K: Motor function assessment in acute inflammation model mice and normal mice three days after transplantation of

two different mitochondria, with untreated groups as control.

ns = no statistical significance,  $* = p<0.05$ ,  $** =$ p<0.01, \*\*\* = p<0.001, \*\*\*\* = p<0.0001

Co-culturing mitochondria from each group with normal BMDM enhanced their bioenergetic capacity, with the Wild Mice group showing the most significant ATP increase (Figure 5C). Both mitochondrial types improved cell viability in LPS-treated BMDM and reduced mitochondrial ROS production, with the Wild Mice group demonstrating better oxidative stress relief and cell viability enhancement (Figures 7L-7N). The second animal experiment provided a more comprehensive validation. While the Young C57 group showed good results, the Wild Mice group exhibited superior therapeutic effects in the acute inflammation model and LPS-treated BMDM, further enhancing cellular bioenergetics and demonstrating the potential of mitochondrial transplantation in boosting biological function.

**Figure 7:** Mitochondrial transplantation enhances biological potency in mice.

# **Outcomes**

- A-C Changes in serum levels of IL-6, TNF-α, and IL-10 in acute inflammation model mice and normal mice one week after transplantation of two different mitochondria, with untreated groups as control.
- D-F Evaluation of kidney and liver function via serum Cr, ALT, and AST levels in acute inflammation model mice and normal mice one week after transplantation of two different mitochondria, with untreated groups as control.
- G-H: Measurement of serum MDA levels and SOD activity in acute inflammation model mice and normal mice one week after transplantation of two different mitochondria, with untreated groups as control.
- I-K: Analysis of JNK and P-JNK, p65, and P-p65 protein expression levels in liver and kidney tissues via Western blot one week after transplantation of two different mitochondria in acute inflammation model mice and normal mice, with untreated groups as control.
- L Effects of two different mitochondria on the viability of LPS-treated BMDM cells 24 hours after transplantation, with untreated groups as control.
- M-N Fluorescence imaging and quantitative analysis of mitochondrial ROS levels in LPS-treated BMDM cells 24 hours after transplantation of two different mitochondria, with untreated groups as control. Scale bar: 30 um.

ns = no statistical significance,  $* = p < 0.05$ ,  $** =$  $p<0.01$ , \*\*\* =  $p<0.001$ , \*\*\*\* =  $p<0.0001$ 

# **Results and Discussion**

The endosymbiotic nature of mitochondria grants them a unique non-immunogenic profile. The adaptation of organisms to their environments has resulted in mitochondria with unique functions, such as cytoplasmic male sterility in plants and drug resistance in eukaryotic cells, both of which are associated with mt DNA. Some mitochondrial functions remain unexplained, yet this does not hinder our exploration of mitochondrial transplantation [62-64]. Transplanted mitochondria need to be metabolically compatible with recipient cells. If recipient cells acquire exogenous mitochondria with lineage-specific characteristics that match their metabolism and can adapt to different stimuli, could we harness different functions from mitochondria of various lineages? Could we, by extension, fuse and absorb unique functions from diverse organisms to accelerate evolution? Given that cells develop tolerance to various stimuli and drugs, could mitochondrial transplantation also develop tolerance? Repeated transplantation of the same type of mitochondria may gradually diminish its effects. Could we, therefore, obtain more potent mitochondria to avoid tolerance and allow the recipient to gradually adapt and enhance biological functions?

Therefore, I designed a series of experiments. The successful internalization of 14 different biological mitochondria by 3 types of cells, compared to previous studies, further confirms the universality and safety of mitochondrial transplantation, while expanding the sources of mitochondria. I hope this can provide patients with more diverse options. I further used 3 cell types and 4 disease models in various combinations to explore the possibility of merging mitochondrial characteristics from different sources. It appears that the source of mitochondria is not significantly restricted, allowing us to screen for mitochondria from different species that are more metabolically compatible and suitable for disease treatment. Since we can assimilate the characteristics of one type of mitochondria, we might also be able to assimilate the characteristics of multiple types. The hybrid mitochondria from HL1 and H9C2 lines exhibited stronger therapeutic effects compared to either HL1 or H9C2 alone, suggesting that it might be possible to artificially create such hybrid mitochondria to target specific diseases. For example, mitochondria from scavengers like Komodo dragons and vultures might have enhanced antibacterial capabilities, while those from honey badgers or mongoose could possess better antivenom properties. We could potentially combine these characteristics for targeted therapies, or even create multi- species hybrid mitochondria similar to multi-drug-resistant bacteria as a universal therapeutic approach. However, these approaches are based on the premise that the functional differences between the mitochondria used are not significant. For the average patient, single-lineage mitochondrial matching might be more appropriate due to safety concerns. As we aim to explore the potential of mitochondrial transplantation and find better therapeutic methods, I have further demonstrated the significant advantages of powerful mitochondria over metabolic matching in

mitochondrial transplantation. These results suggest that the primary therapeutic effect of mitochondrial transplantation may be more related to the rescue of bioenergetics, with changes in cellular metabolism and proteomics being secondary.

We did not perform mitochondrial transplantation on the same batch of cells under different stimuli because the biological function of mitochondria is more critical than metabolic matching. Future research should focus on identifying more potent mitochondria for therapeutic applications. Although metabolic matching is currently important, especially from a safety perspective, it can serve as a foundation for mitochondrial fusion experiments to explore diverse biological therapies. In an artificially cultured environment, especially in stem cells where mitochondrial DNA oxidative damage accumulates less, the significant functional advantages of potent mitochondria may outweigh this benefit. While stem cells are a suitable source due to safety considerations, I believe that future mitochondrial transplantation would be more effective when based on a background of multiple germline sources, optimizing treatment options for metabolic matching. I cannot guarantee the absolute correctness of the current experiments, as the cumulative quantitative changes from multi-lineage hybrid mitochondrial transplantation might surpass the benefits brought by mitochondrial quality itself. Even now, I wouldn't claim that my research is entirely accurate; my experiments emphasize the possibilities of the future, particularly the potential for bio-enhancement.

The results of animal experiments were largely consistent with those of cell experiments, where mitochondria with various functional strengths demonstrated significant therapeutic effects. Notably, Wild Mice mitochondria were more effective in disease model mice and cells compared to other mitochondria. Although the Trained C57 mitochondria did not exhibit the same pronounced therapeutic effects as Wild Mice, their overall therapeutic enhancement was superior to other groups. The Trained People mitochondria did not show the expected therapeutic outcomes, which I attribute to my own suboptimal health due to prolonged lab work, leading to a slightly weaker enhancement of mitochondrial function compared to Trained C57. However, neither Young C57 nor Trained People mitochondria showed a significant difference in therapeutic effect compared to C2C12, suggesting that in vivo mitochondria might compensate for the lower therapeutic efficacy associated with lower DNA oxidative damage in cellular mitochondria. We also observed an enhancement in the biological functions of normal cells by Wild Mice mitochondria, even improving the physiological functions of normal mice to some extent. Additionally, in these two mitochondrial transplantation pre-treatment cell experiments, we observed an increase in recipient cell ATP energy as mitochondrial function improved. This suggests a new solution to mitochondrial transplantation tolerance and potentially an optimized approach for multiple mitochondrial transplants. Importantly, our current results do not indicate a limit to the therapeutic effects of mitochondrial transplantation, implying that we can continue to explore more powerful mitochondria to better assist in treatment, and potentially even enhance human biological functions to some extent. This represents a significant expansion of the implications of mitochondrial transplantation, and I believe that my research could provide stronger and more diverse therapeutic options for clinical applications.

# **Methods**

# **Cell lines**

Bovine kidney cells, porcine kidney cells, African green monkey kidney cells, feline kidney cells, canine kidney cells, human cardiomyocytes, rat cardiomyocytes, mouse cardiomyocytes, and human hepatocellular carcinoma cells were obtained from the Cell Center of the Chinese Academy of Sciences (China). Chicken hepatocellular carcinoma cells were purchased from Sunncell (China), and Spodoptera frugiperda cells and mouse fibroblasts were purchased from Procell (China). The bovine kidney cells, porcine kidney cells, African green monkey kidney cells, feline kidney cells, canine kidney cells, chicken hepatocellular carcinoma cells, human cardiomyocytes, rat cardiomyocytes, mouse cardiomyocytes, mouse myoblasts, and human hepatocellular carcinoma cells were cultured in Dulbecco's Modified Eagle Medium (DMEM) (Gibco) supplemented with 10% (v/v) fetal bovine serum (Gibco) and 1% (v/v) penicillin-streptomycin (Gibco) and incubated at 37°C in a humidified atmosphere with 5%  $CO<sub>2</sub>$ . Spodoptera frugiperda cells were cultured in SF-900TM II SEM (Gibco) medium in a shaker flask at 28°C.

# **Animals**

The animal experiments involved in this study were all C57 B/L 6J strains purchased from the Animal Protection Center of Southern Medical University. All mice were maintained in a specific pathogenfree SPF environment. All mice were used in accordance with the scheme approved by the Review

Committee of Southern Medical University. The mouse experimental scheme has been approved by the Animal Care and Use Committee of Southern Medical University, and the experimental animal facilities have been licensed by the Guangdong Medical Experimental Animal Center (SCXK-2021- 0041). Lizards, salmon, bullfrogs, parakeets, turtles, and eels were purchased from animal breeding markets. Wild mice were captured using traps in the wild, disinfected, and then housed in the laboratory under appropriate conditions.

## **Human subjects**

The human subject involved in this study was the author. Full informed consent was obtained, and muscle tissue was surgically collected from the gastrocnemius muscle following ethical guidelines approved by the Ethics Review Board of Southern Medical University.

# **Plants**

*Vaucheria litorea* was collected and transported under expert supervision and used immediately after thorough disinfection.

# **Isolation of mouse Bone Marrow-Derived Macrophages (BMDMs)**

Bones were aseptically harvested from the hind legs of C57BL/6 mice, and muscle tissues were removed. Bone marrow was flushed out of the bones using a 25-gauge needle attached to a syringe containing BMDM growth medium, which consists of DMEM, 20% L929 cell- conditioned medium to generate M-CSF, 10% FBS, and 1% penicillin/streptomycin. BMDMs were allowed to differentiate for 7 days at 37°C with 5%  $CO<sub>2</sub>$ , with the growth medium changed every 2 days during ex vivo culture.

# **Establishment of cell disease models**

Oxidative stress models were established by treating AC16 with 500  $\mu$ M H<sub>2</sub>O<sub>2</sub> for 24 hours and HepG2 cells with 700  $\mu$ M H<sub>2</sub>O<sub>2</sub> for 24 hours. Inflammation models were established by treating BMDM cells with 100nM LPS for 24 hours and HepG2 cells with 1 µM LPS for 24 hours. Mitophagy models were established by treating AC16 and HepG2 cells with 30 µM CCCP for 24 hours. Senescence model was established by treating HepG2 cells with 30 g/L D-gal for 48 hours.

# **Disinfection and sterilization of plant mitochondria**

Weigh 1g of tissue and rinse with clean water for 3 hours. Transfer to a laminar flow hood, soak in 75% ethanol for 1 minute, then wash twice with DPBS containing 1% streptomycin/penicillin. After soaking in 2% sodium hypochlorite (NaClO) for 8 minutes, wash three times with DPBS containing 1% streptomycin/penicillin for 1 minute each time. Then, rinse repeatedly in  $1\%$  MgCl<sub>2</sub> solution for  $10$ minutes. After that, wash three times with DPBS containing 1% streptomycin/penicillin. Place the sterilized tissue blocks into a 100 mm² culture dish (Corning) and cut them into 0.1 cm² pieces for further use.

# **Mitochondrial isolation**

Mitochondria were isolated from cultured cells, animal tissues, and plant tissues using the Mitochondria-Cytosol Protein Isolation Kit (C0010-50, Applygen) and the Plant Mitochondrial Extraction Kit (SM0020, Solarbio). For tissue homogenization, 100 mg–200 mg of fresh animal tissue or 1 g of plant tissue was cut into 0.5 cm² pieces and placed into a Teflon-glass homogenizer with 2.5 ml of ice-cold mitochondrial extraction buffer. The tissue was homogenized 20 times using a tight-fitting pestle. For cell homogenization,  $2.5\times 10^7$  cells were collected, digested, centrifuged, washed, and resuspended in 1.5 ml of ice- cold mitochondrial extraction buffer. The cell suspension was transferred to a small glass homogenizer and homogenized 30 times using a tight-fitting pestle. The homogenate was transferred to a centrifuge tube and centrifuged at  $800 \times g$  for 5 minutes at 4°C. The supernatant was collected and transferred to a new centrifuge tube and centrifuged at  $10,000 \times g$ for 10 minutes at 4°C. The mitochondrial pellet was resuspended in 0.2 ml of mitochondrial extraction buffer, followed by centrifugation at  $12,000 \times g$  for 10 minutes at 4°C. The supernatant was discarded, and the mitochondrial pellet was resuspended in mitochondrial respiration buffer for subsequent use.

#### **Mitochondrial quality control**

The extracted mitochondria were quantified using a BCA Protein Assay Kit (23250, ThermoFisher). The integrity of the isolated mitochondria was assessed using the Mitochondrial Complex I(E-BC-K151-M , Elabscience) and III Activity Assay Kit (E-BC- K149-M , Elabscience), the mitochondrial membrane potential was measured using the Mitochondrial Membrane Potential Assay Kit with JC-1 (C2006, Byeotime), and the energy synthesis capacity was evaluated using an ATP Assay Kit (S0026, Byeotime).

# **Electron microscopy**

For Transmission Electron Microscopy (TEM), the isolated mitochondria were fixed overnight in 0.2 M sodium cacodylate buffer containing 2.5% formaldehyde, 5% glutaraldehyde, and 0.06% picric acid at pH 7.4. The samples were washed in cacodylate buffer, stained with 1% osmium tetroxide and 1.5% potassium ferricyanide, and then dehydrated using ethanol and propylene oxide. After infiltration and embedding in Epon- Araldite (Electron Microscopy Sciences, Hatfield, PA), sections (60 nm-80 nm thick) were cut using an Ultracut-S ultramicrotome (Reichert Technologies, Depew, NY) and mounted on copper grids (200 mesh) for observation with a transmission electron microscope (Hitachi H-7500).

# **Mitochondrial transplantation in cells**

After mitochondrial isolation, the mitochondria were quantified using a BCA Protein Assay Kit (23250, ThermoFisher). For co-culture, 10 µg of mitochondria were added per 107 cells. For competitive mitochondrial internalization, 1 µg of mitochondria was added per 107 cells, with 0.5 µg of each type for dual mitochondrial competition or 0.33 µg of each type for triple mitochondrial competition.

# **Mitochondrial internalization and observation**

Recipient cell membranes were labeled with WGA594 or WGA488, and the isolated exogenous mitochondria were labeled with MitoTracker™ Green FM or MitoTracker™ Red CMXRos. Both the cells and the exogenous mitochondria were washed twice with DPBS after 30 minutes. The mitochondria and cells were co-cultured for 24 hours in confocal dishes, fixed with paraformaldehyde containing DAPI, washed twice with DPBS, and observed using an inverted laser confocal microscope (LSM900 with Airyscan2, Zeiss).

## **ATP content measurement**

ATP content was measured using an ATP Assay Kit (S0026, Beyotime) following the manufacturer's instructions. One hundred micrograms of isolated mitochondria or cells seeded in a 6-well plate (at a density of  $5 \times 10^7$  cells/well) were treated with 200 μL of ATP lysis buffer, centrifuged at  $12,000 \times$  g for 5 minutes at 4°C. Twenty microliters of supernatant were mixed with 100 μL of ATP detection solution in a 96-well white solid flat-bottom polystyrene microplate (Corning) and the luminescence (RLU) was measured using a multifunctional microplate reader (Tecan).

# **Mitochondrial membrane potential fluorescence quantification**

The isolated mitochondria were subjected to protein quantification, followed by mitochondrial membrane potential assessment using the Mitochondrial Membrane Potential Assay Kit with JC-1 (C2006, Byeotime). In brief, 50 µg of mitochondria were mixed with 90  $\mu$ L of JC-1 staining solution (2  $\mu$ M) and seeded into a 96-well plate. The mixture was thoroughly mixed, and the membrane potential was immediately measured using the BioTek Cytation5 Multifunctional Cell Imaging Microplate Reader (Agilent), with an excitation wavelength of 485 nm and an emission wavelength of 590 nm.

# **Measurement of intracellular reactive oxygen species**

Cells were seeded at a density of  $1 \times 10^7$  cells/well in a 24-well plate. After treating the cells with the respective conditions, exogenous mitochondria were co-cultured with the cells for 24 hours. The medium was then removed, and the cells were washed twice with DPBS. The cells were incubated with 10 µM DCFH-DA (Beyotime) or 5 µM MitoSOX Red at 37°C for 30 minutes. The stained cells were washed with PBS and observed using an inverted laser scanning confocal microscope (LSM900 with Airyscan2, Zeiss) or an inverted fluorescence microscope (EVOS M5000, ThermoFisher). The mitochondrial ROS fluorescence intensity was measured using a multifunctional microplate reader (Tecan) with an excitation wavelength of 510 nm and an emission wavelength of 580 nm.

# **Measurement of mitochondrial membrane potential**

Cells were seeded at a density of  $1 \times 10^7$  cells/well in a 24-well plate. After treating the cells with the respective conditions, exogenous mitochondria were co-cultured with the cells for 24 hours. The medium was then removed, and the cells were washed twice with DPBS. Following the Mitochondrial Membrane Potential Assay Kit with JC-1 protocol, 500 µL of JC-1 staining solution (2 µM) was added to each well and incubated for 20 minutes. The cells were then washed and observed using an inverted laser scanning confocal microscope (LSM900 with Airyscan2, Zeiss) or an inverted fluorescence microscope (EVOS M5000, ThermoFisher) in phenol-red-free DMEM (Invitrogen).

# **CCK8 assay**

According to the Cell Counting Kit-8 (C0037, Beyotime) protocol, 100 µL of cell suspension (density of  $1\times10^4$ ) was seeded in a 96-well plate. After treating the cells with the respective conditions, 10 µL of CCK8 reagent was added, and the cells were incubated at 37°C for 2 hours. The absorbance at 450 nm was measured using a multifunctional microplate reader (Tecan). The percentage of cell viability was calculated based on the average Optical Density (OD) of each group.

# **DNA oxidative damage detection**

The supernatant of the cultured cells was collected 24 hours after mitochondrial transplantation. The 8-OHdG concentration was measured using the 8-OHdG ELISA Kit (E-EL-0028, Elabscience), and absorbance at 450 nm was recorded to quantify DNA oxidative damage.

# **Immunoinflammatory cytokines detection**

The supernatant of the cultured cells was collected 24 hours after mitochondrial transplantation. The concentrations of IL-6, IL-10, and TNF-α were measured using the Mouse IL-6 ELISA Kit (PI326, Byeotime), Mouse IL-10 ELISA Kit (PI522, Byeotime), and Mouse TNF-α ELISA Kit (PT512, Byeotime), respectively, according to the manufacturer's instructions, with absorbance at 450 nm.

# **Measurement of NOS, MDA, GSH, SOD, ALT, AST, Cr**

The supernatants of cultured cells postmitochondrial transplantation or serum from model mice were collected. According to the manufacturer's instructions (NJJCBIO), the OD values for NOS(A014-2-2), MDA(A003-1-2), GSH(A005-1-2), SOD(A001-2-2), ALT(C010-2-1), AST(C009-2-1), and Cr(C011-2-1) were measured at 550 nm, 532 nm, 412 nm, 550 nm, 505 nm, 510 nm, and 546 nm, respectively.

### **Cell fusion**

When cells reached high proliferation rates and good condition,  $3\times10^6$  HL-1 and H9C2 cells were harvested separately. HL1 cells were stained with WGA647 and H9C2 cells with WGA594. The staining was performed at 37°C for 25 minutes, followed by two washes with DPBS. The cells were then mixed and centrifuged at 200 g for 5 minutes. The supernatant was removed, and pre-warmed 50% PEG1450 (P7181, Sigma) was gradually added while stirring the pellet. A total of 700 µL of 50% PEG1450 was added within 1 minute. The mixture was incubated at 37°C for 1 minute, and then 10 mL of DMEM was added to dilute the PEG1450. The centrifuge tube was placed in a 37°C incubator for 10 minutes before being centrifuged again at 200 g for 5 minutes. The cells were washed twice with DPBS, resuspended in complete culture medium, and incubated at  $37^{\circ}$ C with  $5\%$  CO<sub>2</sub> for 24-48 hours. Cell fusion was observed using an inverted laser scanning confocal microscope (LSM900 with Airyscan2, Zeiss), and fused HL1+H9C2 cells were sorted using a MoFlow XDP flow sorter (Beckman)

#### for further culture.

#### **Mitochondrial competitive internalization**

For two types of mitochondrial competitive internalization, the mitochondria were stained with MitoTracker™ Deep Red FM and MitoTracker™ Green FM for 30 minutes, washed twice with DPBS, and co-cultured with recipient cells for 24 hours. The medium was replaced with phenol-red-free culture medium containing ProlongTM antifade reagent, and live-cell imaging was performed using an inverted laser scanning confocal microscope (LSM900 with Airyscan2, Zeiss). For three types of mitochondrial competitive internalization, mitochondria were stained with MitoTracker™ Deep Red FM, MitoTracker™ Green FM, and MitoTracker™ Red CMXRos for 30 minutes, washed twice with DPBS, and co-cultured with recipient cells for 24 hours. The medium was then replaced, and live-cell imaging was performed under the same conditions.

#### **HIIT functional training**

Six-month-old mice underwent one week of preconditioning exercise using a small animal treadmill (XR-PT-10B, Shxinruan) before beginning an 8-weeks HIIT training regimen. The maximum exercise capacity was tested weekly to adjust running speed. Each session began with a 10-minute warmup at a speed of 10 m/min. For the first two weeks, the regimen included high-intensity exercise at 24 m/min (80%  $VO<sub>2</sub>$ max) for 3 minutes, followed by 3 minutes of low-intensity recovery at 15 m/min with a 0° incline. In weeks 3-4, the regimen increased to 26 m/min (80%  $VO_2$ max) for 3 minutes and 15 m/min for 3 minutes at an 8° incline. In weeks 5-6, the speed was further increased to 28 m/min (80% VO<sub>2</sub>max) for 3 minutes, followed by 17 m/min for 3 minutes at a 16° incline. Finally, in weeks 7-8, the speed reached 30 m/min (80%  $VO_2$ max) for 3 minutes, followed by 17 m/min for 3 minutes at a 25° incline. Each session concluded with 8 minutes at 15 m/min. The regimen consisted of 7 sets (3+3) per session, with each session lasting 1 hour, 5 days per week, with 2 days of rest. Similarly, a 29-years-old healthy human (the author) underwent an 8-week HIIT training program, consisting of a 30-second maximal effort sprint (9+ on the 1– 10 RPE scale) followed by a 4.5-minute low-intensity jog (4–5 on the 1–10 RPE scale), daily for 30 minutes, 5 days per week, with an additional 2 days of MICT running at 15 km/h for 30 minutes.

# **Aging model**

Two categories were used: disease-induced and normal aging. For the disease-induced model, 54 two-months-old C57BL/6J mice were divided into groups: D-gal, C2C12, Young C57, Trained People, Trained C57, and Wild Mice. Aging was induced by subcutaneous injection of D-gal at a dose of 500 mg/kg, once daily for 8 weeks. For the normal aging model, 27 four-months-old C57BL/6J mice were divided into Control, Young C57, and Wild Mice groups, with no drug treatment, and were kept under standard conditions.

#### **Acute inflammation model**

Two categories were used. For the inflammation model, 27 four-months-old C57BL/6J mice were divided into LPS, Young C57, and Wild Mice groups. Acute inflammation was induced by intraperitoneal injection of LPS at a dose of 2.5 mg/kg/day for 5 consecutive days. Another set of 27 four-monthsold C57BL/6J mice was divided into Control, Young C57, and wild mice groups, with no drug treatment and normal rearing.

# **Animal mitochondrial transplantation**

For the aging model, mitochondria were isolated from the gastrocnemius muscle tissues of Young C57, Trained People, Trained C57, and Wild Mice, as well as C2C12 cells, using the Mitochondria-Cytosol Protein Isolation Kit (C0010-50, Applygen). Mitochondrial protein was quantified using the BCA Protein Assay Kit (23250, ThermoFisher). A dose of 100 μL/100 μg of mitochondria was injected via the tail vein into the C2C12, Young C57, Trained People, Trained C57, and Wild Mice groups, while the control group received no treatment. For the normal type, mitochondria from Young C57 and Wild Mice were injected into their respective groups at the same dose, with the control group receiving 100 μL of mitochondrial carrier solution. For the acute inflammation model, mitochondria were isolated from the gastrocnemius muscle of Young C57 and Wild Mice, quantified, and injected via the tail vein at a dose of 100 μL/100 μg into the Young C57 and Wild Mice groups. The LPS group received no treatment, and the control group received 100 μL of mitochondrial carrier solution.

#### **Mitochondrial biodistribution**

Isolated mitochondria were labeled with MitoTracker™ Deep Red FM at room temperature for 20 minutes, washed twice with DPBS, and injected via the tail vein into mice. After 24 hours, the heart, liver, and kidneys were collected, and mitochondrial biodistribution was assessed using a multimodal small animal in vivo imaging system, PerkinElmer IVIS Spectrum (PerkinElmer).

#### **Motor function detection (Rotarod Test)**

Three days prior to the experiment, mice underwent

adaptive training. During the formal experiment, mice were placed on a Rotating rod instrument (XR-6C/XR-6D, Shxinruan) at 5 rpm/min for 5 minutes, then gradually accelerated to 40 rpm/min. The time the mice remained on the rotating rod was recorded using a stopwatch until they fell off. The maximum duration for aging or acute inflammation mice was 180 seconds, with a maximum of 360 seconds for normal mice. Each mouse was tested three times with a 3-minutes interval between trials, ensuring a quiet environment during the experiment.

#### **Body weight measurement**

All experimental groups of mice were weighed 3 days before and 1 week after mitochondrial transplantation, with weights recorded.

#### **Mouse forelimb grip strength test**

Three days prior to the experiment, mice underwent adaptive training. During the formal experiment, each mouse was placed on a Mouse grip tester (XR501, Shxinruan), and gentle traction was applied to the tail, prompting the mouse to grip the probe firmly with its forelimbs. The grip strength reading was recorded when the experimenter applied maximum force, with the experiment conducted in a quiet environment.

# **Lower limb muscle volume and injury assessment**

One week after mitochondrial injection, mice were briefly anesthetized with a mixture of isoflurane  $(3.0\%)$  and  $O<sub>2</sub>$   $(2.0 \text{ L/min})$  via a nose cone and placed in a custom-made restraint tube, with the right lower limb fixed with a coil. During MRI imaging, mice were anesthetized with a mixture of isoflurane (1.5%) and  $O_2$  (0.6 L/min). The rectal temperature was maintained at  $37^{\circ}$ C  $\pm$  1°C using a heated water blanket. A small animal magnetic resonance imaging system, PharmaScan70/16S (Bruker), was used to scan the horizontal plane of lower limb muscles, employing Spin Echo (SE) T1WI (TR4000 ms, TE 28.5 ms), Fast Spin Echo (FSE) T2WI (TR4000 ms, TE 47.5 ms), with a slice thickness of 4 mm and an interval of 1 mm. Process the images using Paravision 6.0.1 (Bruker).

#### **Western blot**

Proteins were extracted from liver and kidney tissues, separated by 10% SDS-PAGE, and transferred onto Polyvinylidene Fluoride (PVDF) membranes. Phosphorylated proteins and total proteins were blocked with 5% BSA and 5% milk, respectively. PVDF membranes were incubated with primary antibodies at 4°C overnight, followed by a 2-hours incubation with HRP-conjugated secondary

antibodies at room temperature. Gel imaging was performed using the Tanon-5200 Multi Automatic Luminous System (Tanon).

### **Quantitative PCR**

Twenty-four hours after mitochondrial transplantation, total RNA was extracted using Trizol reagent. Purified RNA was reverse-transcribed into cDNA using the PrimeScript™ RT reagent Kit (RR037Q, Takara). RT-qPCR was conducted with SYBR Green Master Mix (430915, Invitrogen) using the ABI QuantStudio 5 Real-Time PCR system (ThermoFisher). Expression levels were normalized to the internal control 18s rRNA. The primer sets are listed in key resources table.

# **Conclusion**

# **Quantification and statistical analysis**

Cell experiments were repeated at least three times except for mitochondrial competitive internalization and animal experiments except for body weight measurement, grip strength and motor function tests. GraphPad Prism 9.01(GraphPad Software Inc., San Diego, CA, USA) software was used for statistical analysis. The data were expressed as Mean ± Standard Error (SEM). For normally distributed data and comparisons between two groups, the significance was calculated using unpaired twotailed Student's t-tests. Comparisons between three or more groups were performed using ordinary One-way ANOVA, using two-way ANOVA and Bonferroni post hoc test were used to compare multifactor variance for multiple data. The significance threshold was determined by p value < 0.05, and the annotation was

ns = no statistical significance,  $* = p<0.05$ ,  $** =$  $p < 0.01$ , \*\*\* =  $p < 0.001$ , \*\*\*\* =  $p < 0.0001$ .

# **Acknowledgments**

I sincerely thank the People's Hospital of Dongguan City, affiliated with Southern Medical University, for providing free access to experimental instruments. I also extend our gratitude to Dr. Guiming Chen from

the Department of Pathology and Pathophysiology at Southern Medical University and Dr. Rong Wu from the School of Traditional Chinese Medicine for their technical support with mitochondrial tail vein injections. Additionally, I appreciate the assistance of Master Xin Heng in the experiments involving fluorescence microscopy for detecting reactive oxygen species and mitochondrial membrane potential. Moreover, I express strong condemnation towards those who deliberately sabotage others' experiments. I urge all laboratories to actively remove such unethical individuals. This work was carried out with the author's full commitment, with all funding provided personally by the author. Consequently, there are several limitations in this study, for which we apologize. There are three main reasons why further experiments are challenging for me: first, the experimental cells were deliberately destroyed, preventing continuation; second, it is extremely difficult to obtain mitochondria from HIIT-trained and wild mice; third, and most importantly, there is a lack of funding. Due to my poor English proficiency, this paper was translated from Chinese to English by ChatGPT for submission. If there is anything unclear, please feel free to contact me. Alternatively, you can request the original Chinese manuscript and translate it yourselves. I can also add an additional corresponding author if needed. Let me know if you need any further adjustments! Should additional resources become available, I plan to conduct more detailed research to provide a more comprehensive explanation of my study.

# **Author contribution**

Xiaomeng Lu(fylxmgg@gmail.com) leads all the experimental design, experimental operation, experimental analysis, article writing and proofreading. JiangYong(18675838414@163. com) provided the experimental site and some experimental equipment.

# **Declaration of Interests**

The authors declare no competing interests.
